E-mail: sergei@ku.edu

ABSTRACT: A new semi-analytical model that explains the formation and sizes of the 'great walls' - the largest structures observed in the universe is suggested. Although the basis of the model is the Zel'dovich approximation it has been used in a new way very different from the previous studies. Instead of traditional approach that evaluates the nonlinear density field it has been utilized for identification of the regions in Lagrangian space that after the mapping to real or redshift space (depending on the kind of structure is studied) end up in the regions where shell-crossing occurs. The set of these regions in Lagrangian space form the progenitor of the structure and after the mapping it determines the pattern of the structure in real or redshift space. The particle trajectories have crossed in such regions and the mapping is no longer unique there. The progenitor after mapping makes only one stream in the multi-stream flow regions therefore it does not comprise all the mass. Nevertheless, it approximately retains the shape of the structure. The progenitor of the structure in real space is determined by the linear density field along with two non-Gaussian fields derived from the initial potential. Its shape in Eulerian space is also affected by the displacement field. The progenitor of the structure in redshift space also depends on these fields but in addition it is strongly affected by two anisotropic fields that determine the pattern of great walls as well as their huge sizes. All the fields used in the mappings are derived from the linear potential smoothed at the current scale of nonlinearity which is $R_{nl} = 2.7 h^{-1}\text{Mpc}$ for the adopted parameters of the ΛCDM universe normalized to $\sigma_8 = 0.8$. The model predicts the existence of walls with sizes significantly greater than $500 h^{-1}\text{Mpc}$ that may be found in sufficiently large redshift surveys.

1. Introduction

The first indications of the existence of superclusters of galaxies bridging the clusters of galaxies [1, 2] was confirmed by the CfA redshift survey [3]. In the following two decades the discovery of huge concentrations of galaxies spanning over $200 \text{ h}^{-1}\text{Mpc}$ were reported (e.g., [4, 5]). They were dubbed "great walls" due to their sizes and geometry in redshift space. The current record belongs to "a Sloan Great Wall of galaxies 1.37 billion light years long, 80% longer than the Great Wall discovered by Geller and Huchra and therefore the largest observed structure in the universe" [5]. Taking into account that the SDSS redshift survey is much larger and deeper than CfA one may wonder whether the Sloan Great Wall will remain the greatest wall or even greater walls will be found in the future redshift surveys and if it is so how large it may be. The answer to this question may depend to certain extent on the exact definition of the walls. For instance, some definitions may result in the percolating system of filaments and walls that would span throughout the whole volume. However even in this case the essential constituents can be probably identified and measured. We show that by restricting the analysis to the issues of overall geometry and scale of the largest walls one can alleviate some of the problems of this kind and make some progress. In particular, the details of the density distribution within the walls, such as the accurate positions and masses of halos become less important if the scales of interest exceeds $\sim 10 \text{ h}^{-1}\text{Mpc}$.

We begin with a brief discussion of the structure in real space. The scale separating the nonlinear regime of the gravitational growth from linear or mildly nonlinear regimes

is roughly around $5 \text{ h}^{-1}\text{Mpc}$ which is close to the galaxy correlation scale. It seems to be by far too small to be directly relevant to the scale of filaments some of them are at least $70 - 100 \text{ h}^{-1}\text{Mpc}$ long. Bond, Kofman and Pogosyan [6] (hereafter BKP) suggested that the filamentary network in real space with a typical scale of $\sim 30 \text{ h}^{-1}\text{Mpc}$ can be explained by invoking the correlation bridges between relatively high and therefore rare peaks in the linear density field filtered on scales greater than R_b such that $\sigma_\rho(R_b) \lesssim 1$. Unfortunately, the BKP model has not provided a framework for a quantitative evaluation of the density contrast in the filaments bridging the clusters of galaxies from the enhancement of the conditional correlation function between two or more peaks. Besides, the gravitational growth of the structure in the universe is a deterministic process if the linear perturbation field is specified. Therefore, one may seek a deterministic relation between the initial field and the final structure at least in cosmological simulations where the full information is available. In addition, the cluster analysis of the nonlinear dark matter density field in real space obtained by N-body simulation in the ΛCDM model [7] revealed the filaments with lengths up to $\sim 100 \text{ h}^{-1}\text{Mpc}$ [8] i.e., significantly greater than $30 \text{ h}^{-1}\text{Mpc}$. A similar analysis of the mock galaxy catalogs [9] demonstrated the presence of even longer filaments in redshift space, up to $\sim 150 \text{ h}^{-1}\text{Mpc}$ [10]. Both numbers are almost certainly affected by the simulation box sizes ($240 \text{ h}^{-1}\text{Mpc}$ in the former and $346 \text{ h}^{-1}\text{Mpc}$ in the latter case) and could be even longer in larger boxes. The simulated dark matter density fields and especially mock galaxy catalogs look similar to the observed distribution of galaxies as well as they have similar statistics of various kinds that makes the model viable. However, the emergence of the nonlinear structures (great walls) $\sim 50 - 100$ times greater than the scale of nonlinearity remains unexplained even in the cosmological N-body simulations where the full information about the both initial conditions and formed structure is available.

It has been realized for a long time that the structures in real space and observed in redshift space have different pdfs, power spectra, correlation functions, and higher order moments (e.g., [11, 12, 13, 14, 15, 16]). The redshift-space correlation function has an oblate shape on scales greater than a few h^{-1}Mpc indicating the presence of anisotropic structures in redshift space flattened in the radial direction. However, the measurements do not go beyond $\sim 30 \text{ h}^{-1}\text{Mpc}$ where the correlation function drops to ~ 0.1 and the signal drowns in noise [16]. Theory has not made any specific predictions concerning the structure in the universe on scales greater than $100 \text{ h}^{-1}\text{Mpc}$ therefore the conventional wisdom is that the perturbations on such scales must be in the linear regime.

The 'finger of God' is the most conspicuous and best understood effect in redshift space. However, it is a relatively small scale effect and cannot explain the coherence of the great walls over a few hundred h^{-1}Mpc . It has been also demonstrated in [17, 18] that the size of the structures in the redshift space is considerably greater than that of the parent structures in real space. In addition, the authors emphasized a characteristic circular pattern in redshift space and the increased spacing between the structures in the redshift direction. However, they neither mentioned the enlargement of sizes of the structures in the transverse direction nor provided explanation to their observations.

The presence of walls up to $150 \text{ h}^{-1}\text{Mpc}$ in length in redshift space in three-dimensional simulations based on the adhesion approximation was emphasized in [19]. The authors

pointed out that the correlation function was weak or even negative at these scales. They also observed that $\sim 100 \text{ h}^{-1}\text{Mpc}$ walls grow from several favorably aligned high-density peaks in the linear density field, each coherent over $\sim 20 \text{ h}^{-1}\text{Mpc}$. This seems to be a factual description of the process, however similarly to the BKP model it requires a dynamical model different from the linear theory of gravitational instability. The major problem with the structures spanning over $\sim 300 \text{ h}^{-1}\text{Mpc}$ arises from a lack of a natural scale of this magnitude in the linear density field. If the field is smoothed with say $100 \text{ h}^{-1}\text{Mpc}$ or greater scale than its amplitude becomes so low that such a field would remain almost perfectly linear at the present time.

We view the formation of the structure as a continuous mapping from the initial practically uniform state in Lagrangian space to the final highly inhomogeneous and anisotropic distribution of mass on scales up to $\sim 100 \text{ h}^{-1}\text{Mpc}$ in Eulerian space followed by another mapping to redshift space where the largest structures become greater than $300 \text{ h}^{-1}\text{Mpc}$. These mappings involve the transport of mass (although not physical in the case of the mapping to redshift space), however the rms displacement of mass elements is only about $15 \text{ h}^{-1}\text{Mpc}$ and therefore it cannot produce the structures of needed sizes by itself. Thus, the certain initial fields i.e., the fields present in the linear stage and playing an important role in the nonlinear dynamics must have scales in the range of $100 \text{ h}^{-1}\text{Mpc}$ or even greater. The major goal of this paper is to show that the fields having needed properties exist in Lagrangian space. The outcome of their combined effect is the definition of two parent structures that are the progenitors of the large-scale structures: one in real and the other in redshift space. Being closely related two progenitors are still quite distinct. The properties of the progenitors are determined by a combination of Gaussian and non-Gaussian fields derived from the initial gravitational potential smoothed with a Gaussian filter at the scale of nonlinearity R_{nl} defined by the equation $\langle \delta_{\text{lin}}^2(R_{\text{nl}}) \rangle = 1$, where $\delta \equiv \delta\rho/\bar{\rho}$. In the standard ΛCDM model normalized to $\sigma_8 \approx 0.8$ this scale is $R_{\text{nl}} = 2.7 \text{ h}^{-1}\text{Mpc}$. The choice of the filter and filtering scale for 2D illustrations approximately corresponds to an optimal choice of the filter and scale in 3D simulations that studied the accuracy of the Truncated Zel'dovich Approximation (TZA) in a set of power law models in the Einstein-de Sitter model [22]. Some adjustment will be probably needed for the ΛCDM model in 3D. Based on that study I would conservatively guess that the change in R_{nl} would not be greater than 30%. No fields smoothed at greater scales are involved in the mapping. The structure resulting from the mapping of the progenitors cannot and is not supposed to reproduce accurately the mass or galaxy number densities, however the overall shape and sizes of the structure in real space and great walls in redshift space must be depicted quite well.

We use TZA as a mapping device for both mapping [20, 22, 21, 15]. In this paper we will concentrate on the lengths of the progenitors in the Lagrangian space and their transformation caused by the mapping to Eulerian and redshift space.

We illustrate the model by two-dimensional plots. Although no two-dimensional model can reproduce all the properties of a three-dimensional system it may provide a reasonably good description of major ideas. In order to make the appearance of illustrations more realistic we use the linear power spectrum $P^{2D}(k) = k P^{3D}(k)$, where $P^{3D}(k)$ is the power spectrum of the linear density perturbations in the ΛCDM model with parameters $h = 0.7$,

$\Omega_m = 0.3$, $\Omega_b = 0.047$, $n = 1$. We use the BBKS transfer function [23] with the Γ -parameter given by [24]. This choice of two-dimensional power spectrum retains all the moments $\langle k^j \rangle$ of the three-dimensional spectrum and therefore all the scales of the two-dimensional field determined by the ratio of two moments (e.g., the scale of peaks $R_*^2 \sim \langle k^2 \rangle / \langle k^4 \rangle$) remain similar to that of the three-dimensional field except a small factor $\sqrt{3/2} = 1.2$. The two-dimensional fields were generated in $1024 \text{ h}^{-1}\text{Mpc}$ box on 1024^2 mesh.

The rest of the paper is organized as follows. Section 2 outlines the dynamical model and fields involved in both mappings. Section 3 provides two dimensional illustrations that elucidate the main concepts of the model, the axes in the figures showing various fields are given in h^{-1}Mpc . Section 4 discuss the differences between 2D and 3D cases, Sec. 5 summarizes the results and outline the further problems, finally the appendix gives the joint density probability function of three invariants of the deformation tensor that are used in the mappings.

2. Model

The dominant feature of the process of the structure formation is usually dubbed as the hierarchical clustering. It simply means that small halos generally form earlier than the larger ones. Thus, more massive halos are formed by consecutive merging of smaller halos. The merging process effectively stops on the scale of R_{nl} or on a little greater scale. It is a well established fact that the formation of the structures on larger scales is mainly determined by the long wave part of the initial spectrum with $k < R_{\text{nl}}^{-1}$ [25]. [25] also pointed out that the changes in the high-frequency ($k > R_{\text{nl}}^{-1}$) components of the initial conditions did not affect much the evolution of long waves. A direct comparison of the nonlinear density fields obtained in the N-body simulations of models with and without high-frequency components (Truncated Zel'dovich Approximation) in the initial conditions has also shown a very good agreement [20, 22, 21]. In general, the Zel'dovich approximation "gives a reasonable description of the overall pattern of N-body simulations" [6].

Using the comoving coordinates $\vec{x} \equiv \mathbf{r}/a(t)$ where $a(t)$ is the scale factor describing the uniform expansion of the universe the Zel'dovich approximation [26] (see also [27]) becomes

$$x_i(\mathbf{q}, t) = q_i + D(t)s_i(\mathbf{q}), \quad (2.1)$$

where vector $\mathbf{q}$ gives the Lagrangian (initial) position of a fluid element, $\mathbf{x}$ is the Eulerian position of the fluid element at time t , $D(t)$ describes the linear growing mode of fluctuations, $s_i(\mathbf{q}) = -\partial\Phi/\partial q_i$ is the displacement field and $\Phi(\mathbf{q})$ is the linear gravitational potential field. Thus, our dynamical model is the Zel'dovich approximation applied to the initial fluctuation field smoothed over the nonlinear scale R_{nl} which equals $2.7 \text{ h}^{-1}\text{Mpc}$ in the ΛCDM model normalized to $\sigma_8 = 0.8$.

Instead of traditional approach that tries to evaluate the evolution of density field we suggest to consider its inverse i.e., the evolution of specific volume $V = \rho^{-1}$. The specific volume is more suitable quantity for our purpose because it allows an easy separation of the effects related to various fields. We would like to remind that we do not use this model

for accurate predicting of the nonlinear density field but only for approximate identification of high density regions. The specific volume is given by the Jacobian

$$\frac{V_x(\mathbf{q}, t)}{\langle V \rangle} = J_x = \det \left(\frac{\partial x_i}{\partial q_j} \right). \quad (2.2)$$

The growth of density corresponds to the decrease of the specific volume. Some fluid elements may collapse to zero volume and at later time their volumes predicted by eq. 2.2 become even negative however this is an easy problem. Negativeness of the density or specific volume simply reflects the fact that such a fluid element turns inside out and the positiveness of the density can be easily restored by taking the absolute value of the Jacobian. It also indicates that the trajectories of fluid elements are crossed and the mapping is no longer unique. This creates a much more serious problem that does not have a simple solution even in the frame of the Zel'dovich approximation (apart from breaking the approximation within the regions where shell-crossing occurs) mainly because the problem becomes nonlocal. The set of fluid elements that collapse by the present time form a structure in Lagrangian space, we shall call it the progenitor or parent structure. The parent structure mapped to Eulerian space by means of eq. 2.1 forms the pattern of the large-scale structure. It is worth stressing that the parent elements do not represent the total mass contained in the large-scale structure however they approximately mark the regions of highest density. The situation becomes more complex if we recall that the large-scale structure forms from highly nonuniform state where practically all the mass is already in the form of virialized halos. However, as the previous studies showed (e.g., [27, 25, 20, 22, 21]) the overall distribution of the halo number density corresponds to this model quite well.

The Jacobian can be expressed in terms of the invariants (I_1, I_2, I_3) or eigen values ($\lambda_1, \lambda_2, \lambda_3$) of the deformation tensor $d_{ij} = -\partial s_i / \partial q_j = \partial^2 \Phi / \partial q_i \partial q_j$

$$\begin{aligned} J_x(\mathbf{q}, t) &= 1 - D(t)I_1(\mathbf{q}) + D^2(t)I_2(\mathbf{q}) - D^3(t)I_3(\mathbf{q}) \\ &= [1 - D(t)\lambda_1(\mathbf{q})][1 - D(t)\lambda_2(\mathbf{q})][1 - D(t)\lambda_3(\mathbf{q})], \end{aligned} \quad (2.3)$$

where

$$I_1 = d_{11} + d_{22} + d_{33}, \quad I_2 = M_{11} + M_{22} + M_{33}, \quad I_3 = \begin{vmatrix} d_{11} & d_{12} & d_{13} \\ d_{12} & d_{22} & d_{23} \\ d_{13} & d_{23} & d_{33} \end{vmatrix}, \quad (2.4)$$

and M_{ij} are the minors of the corresponding elements of the determinant I_3 . The eigen values are the solutions of the characteristic equation

$$\lambda^3 - I_1\lambda^2 + I_2\lambda - I_3 = 0. \quad (2.5)$$

It always has three real solutions because the mapping is generated by the potential vector field $s_i(\mathbf{q})$ and therefore the deformation tensor is symmetric $d_{ij} = d_{ji} = \partial^2 \Phi / \partial q_i \partial q_j$; it is convenient to assume the solutions to be ordered at every point $\lambda_1(\mathbf{q}) \geq \lambda_2(\mathbf{q})$ and $\lambda_2(\mathbf{q}) \geq \lambda_3(\mathbf{q})$.

Equation $J_x(\mathbf{q}, t) = 0$ has obviously three solutions for D as well: $D_i = 1/\lambda_i$. If any of them lies in the interval $0 < D_i(\mathbf{q}) < 1$ we consider the fluid element with Lagrangian coordinates $\mathbf{q}$ to belong the progenitor of the structure. Condition $0 < \lambda_1(\mathbf{q}) < 1$ is equivalent to the above condition for $D_i(\mathbf{q})$ but it is less general and cannot be used for the mapping to redshift space where it is not of potential type.

In order to describe the mapping to redshift space (ζ_i) we supplement eq. 2.1 with additional term (see e.g., [15])

$$\zeta_i = x_i + f D s_k(\mathbf{q}) n_k(\mathbf{x}) n_i(\mathbf{x}) = q_i + D s_i(\mathbf{q}) + f D s_k(\mathbf{q}) n_k(\mathbf{x}) n_i(\mathbf{x}) \quad (2.6)$$

where $\mathbf{x}$ is given by eq. 2.1, $f = d \log D / d \log a \approx \Omega_m^{0.6}$ for the present time [11] or a better approximation given in [28]. The unit vector $n_i \equiv x_i/x$ is directed along the line of sight. We assume summation over repeated indices throughout the paper. The peculiar velocity $v_i^{(p)} = \dot{a} f D s_i$ and therefore the displacement of a galaxy from comoving Eulerian position, x_i to redshift space position, ζ_i , is $v_k^{(p)} n_k / (aH) = f D s_k n_k$ along the line of sight. The distances in Lagrangian, comoving Eulerian and redshift space are measured in $h^{-1} \text{Mpc}$.

Figure 1: Lagrangian space. Regions $\delta(\mathbf{q}) > 1$ or equivalently $1 - I_1(\mathbf{q}) < 0$ are shown in green.

The specific volume is equal to the corresponding Jacobian

$$\frac{V_\zeta(\mathbf{q}, t)}{\langle V \rangle} = J_\zeta = \det \left(\frac{\partial \zeta_i}{\partial q_j} \right). \quad (2.7)$$

The evaluation of V_ζ in terms of the initial fields is a quite laborious task. Fortunately it allows a considerable simplification in the limit of $|D\mathbf{s}| \ll q$. Physically it means that the results are not reliable within $50 h^{-1} \text{Mpc}$ or so from the center but it is not very important

since we are interested in much greater scales. The components of the Jacobian become (to the zeroth order in $|D\mathbf{s}|/q$)

$$\frac{\partial \zeta_i}{\partial q_j} \approx \delta_{ij} - D(d_{ij} + f\tilde{n}_i\tilde{n}_kd_{jk}), \quad (2.8)$$

where $\tilde{\mathbf{n}} = \mathbf{q}/q$. Mapping to redshift space is neither irrotational nor solenoidal which means that Jacobian J_ζ has no symmetry. Similarly to the Jacobian of the mapping to Eulerian space the determinant J_ζ can be expressed in terms of the invariants of the initial fields and the radial components of two tensors d_{qq} and M_{qq}

$$J_\zeta = 1 - DI_1 + D^2(1+f)I_2 - D^3(1+f)I_3 - fDd_{qq} - fD^2M_{qq}, \quad (2.9)$$

where $d_{qq} = \tilde{n}_i\tilde{n}_jd_{ij}$ and $M_{qq} = \tilde{n}_i\tilde{n}_jM_{ij}$ are the radial components of the deformation tensor and tensor made of the minors of the determinant I_3 . The invariants are statistically isotropic fields although two of them ($I_2(\mathbf{q})$ and $I_3(\mathbf{q})$) are non-Gaussian. The last two terms depend on highly anisotropic fields: one $d_{qq}(\mathbf{q})$ is Gaussian and the other $M_{qq}(\mathbf{q})$ is non-Gaussian.

3. Two-dimensional illustration

Figure 2: Lagrangian space. Red regions $1 - I_1(\mathbf{q}) + I_2(\mathbf{q}) < 0$, green contours $\delta(\mathbf{q}) = 1$ correspond to the boundaries of the regions in fig. 1.

Major although not all features of the model can be illustrated by a two-dimensional model. Although the main goal of the paper is a study of the mapping to redshift space we

briefly discuss the mapping to real space and show the importance of non-Gaussian fields for building the large-scale structure. We shall use a convenient normalization of function $D(t)$ such that at the present time $D(t_0) = 1$ and the variance of the linear density contrast field $\sigma_\delta^2 = 1$, parameter $f \approx 0.8$ for the chosen cosmological model.

3.1 Mapping to real space

The Jacobian of the mapping to Eulerian space in two dimensions depends on two statistically isotropic and homogeneous fields: one Gaussian $I_1(\mathbf{q})$ and one non-Gaussian $I_2(\mathbf{q})$

$$\frac{V_x}{\langle V \rangle} = J_x = 1 - DI_1 + D^2I_2. \quad (3.1)$$

The initial density contrast field $\delta_{in} \equiv \delta\rho/\bar{\rho} = D(t_{in})I_1$ is assumed to be Gaussian. Let us begin with the linear approximation $V_x/\langle V \rangle = 1 - DI_1$. Linear theory formally predicts that the peaks with $\delta \geq 1$ shrink to the regions having formally negative volumes (and therefore negative density) by the present time. Figure 1 shows an example of the progenitor of the structure in Lagrangian space predicted by the linear theory $V_x(t_0, q)/\langle V \rangle = 1 - D(t_0)I_1(q) = 1 - I_1(q) < 0$. Although the initial power spectrum is filtered with Gaussian windows $\exp(-k^2 R_f^2/2)$ with $R_f = 2.7 \text{ h}^{-1}\text{Mpc}$ some peaks $\delta > 1$ have quite large lengths reaching $\sim 30 \text{ h}^{-1}\text{Mpc}$.

The full nonlinear model $v_x(t_0, q) = 1 - D(t_0)I_1(q) + D^2(t_0)I_2(q) = 1 - I_1(q) + I_2(q) < 0$ predicts the progenitor of the structure shown in Figure 2 in red. The green contours show the boundaries of the linear progenitor shown in fig.1, thus one can see both the similarities and differences of two fields. In order to make an eye ball estimate of sizes easier we plot the grid on the background. The similarity of two fields is obvious but it is not unexpected because both fields depend on $I_1(q)$ and therefore strongly correlated. The effect of non-Gaussian I_2 -field is quite remarkable. The red non-Gaussian regions are considerably longer than the linear density peaks. They also typically comprise several green regions therefore non-Gaussian field I_2 provides "bridges" linking the peaks of linear density contrast field. This is in a good qualitative agreement with the observations made by Weinberg and Gunn [19] who emphasized that the large structures usually consist of several peaks in the linear density field. There is also no contradiction to the role of the correlation between linear density peaks in the BKP model [6], although the higher peaks of the field smoothed with greater scale is assumed in the BKP model. The green contours totally comprise 15.9% of the area. It is remarkable that the red regions where the nonlinear condition $1 - I_1(q) + I_2(q) < 0$ is satisfied occupy slightly less area (15.3%) than the green contours. Despite the greater lengths of the nonlinear progenitor reaching over $100 \text{ h}^{-1}\text{Mpc}$ red regions are generally slimmer than their counterparts in the linear progenitor. The resolution of fig.2 is far too low to reveal this completely. However, it is obvious in fig.3 where the central part of fig.2 is zoomed in. In addition, small isolated regions of the linear progenitor disappear from the nonlinear one (empty green contours).

Figure 4 shows the structure in Eulerian space (red) along with the progenitor in Lagrangian space (green). The mapping makes the structure considerably slimmer than

Figure 3: Lagrangian space, the central $200 \text{ h}^{-1} \text{Mpc}$ box of fig.2. Red regions $1 - I_1(\mathbf{q}) + I_2(\mathbf{q}) < 0$, green contours $\delta(\mathbf{q}) = 1$ correspond to the boundaries of the regions in fig.1.

its progenitor in Lagrangian space although it is probably thicker than in reality [27]. Two points are worth stressing. First, neither lengths of the filaments nor topology visibly change due to mapping itself. And second, the filaments do not move much, however those that moved were are displaced mostly in the transverse direction while the longitudinal displacement is significantly smaller. It is also worth recalling that the r.m.s. displacement of fluid elements from the Lagrangian to Eulerian positions is about $15 \text{ h}^{-1} \text{Mpc}$ which is greater than the thickness of the filaments but considerably smaller than their lengths. The mapping to real space also involves statistically isotropic Gaussian vector field $s_i(\mathbf{q}) = -\partial\Phi/\partial q_i$.

3.2 Mapping to redshift space

We obtain the Jacobian of the mapping to redshift space in two dimensions from eq. 2.9

$$J_\zeta(\mathbf{q}, t) = 1 - DI_1 + D^2(1 + f)I_2 - fDd_{qq}, \quad (3.2)$$

where $I_1 = d_{11} + d_{22}$ and $I_2 = d_{11}d_{22} - d_{12}^2$ are the invariants of the deformation tensor in two dimensions, $d_{qq} = \tilde{n}_1^2 d_{11} + 2\tilde{n}_1\tilde{n}_2 d_{12} + \tilde{n}_2^2 d_{22}$ is the radial component of the deformation tensor. Compared to the mapping to Eulerian space the term proportional to I_2 is boosted by factor $1 + f$. The Jacobian contains a highly anisotropic field $d_{qq}(\mathbf{q})$ in the sense that the contours are significantly longer in the transverse direction than in radial direction as a result the field acquires a characteristic circular pattern (fig.5). The cause of this anisotropy becomes much more obvious if one considers the small angle approximation

Figure 4: Eulerian space. The large-scale structure in Eulerian space (red) and the progenitor of the structure in Lagrangian space (green).

[12]. Now, let us consider the direction corresponding to q_1 -axis. In this case $\tilde{\mathbf{n}} = (1, 0)$ therefore $d_{qq} = d_{11}(q) = \partial^2 \Phi(\mathbf{q}) / \partial q_1^2$. Differentiating potential two times with respect to q_1 multiplies the power spectrum by k_1^4 ($P_{d_{11}}(\mathbf{k}) = k_1^4 P_\Phi(k)$) that effectively reduces the characteristic scale of the resulting field along q_1 direction while the scale along q_2 changes much less. In the case of arbitrary direction the reduction of the scale along radial direction is much stronger than in the transverse direction that generates a distinct circular pattern.

The mapping to redshift space also involves the radial component of the velocity field $v_q(\mathbf{q}) = f D s_q(\mathbf{q}) = -f D \partial \Phi / \partial q$ shown in fig.6. Although the vector field $\mathbf{s}(\mathbf{q})$ itself is isotropic its components are highly anisotropic fields. Again, let us consider the small angle approximation and $v_1(\mathbf{q}) \propto s_1(\mathbf{q})$ component of the velocity vector field. The power spectrum $P_{s_1}(\mathbf{k}) = k_1^2 P_\Phi(k)$ is anisotropic with considerably more power along k_1 direction. Therefore the field $s_1(\mathbf{q})$ has much smaller scale along q_1 direction than along q_2 direction. For an arbitrary direction $\tilde{n}_i = q_i / q$ it is translated into considerable anisotropies between radial and transverse directions. A natural expectation suggests that the structure in redshift space is shifted to the segments of the zero contour $v_q(\mathbf{q}) = 0$ satisfying the convergence condition $\partial v_q / \partial q < 0$ marked by black dots on green contour in fig.6. On the inner side of these segments the radial component of the peculiar velocity is positive and therefore directed away from the center while on the outer side it is negative and thus directed toward the center resulting in shifting mass to these lines by the mapping to redshift space.

The progenitor of the structure in redshift space determined by eq. 3.2 is shown as

Figure 5: Lagrangian space. Contours $fd_{qq}(\mathbf{q}) = 0.25, 0.5, 1$ are shown in blue, green and red respectively.

red regions in fig.7. The green contours show the boundaries of the regions $\delta(\mathbf{q}) > 1$ shown in fig.1 as green regions and also as green contours in fig.2. It is worth comparing the progenitors of the mappings to Eulerian (fig.2) and redshift space (fig.7). The circular pattern due to fDd_{qq} term in eq. 3.2 is quite obvious in fig.7 but it is significantly less conspicuous than in fig.5 because the other two fields (I_1 and I_2) affecting the Jacobian are both statistically isotropic and homogeneous. The black dots mark the lines of convergence defined above and shown in fig.6. The convergence lines obviously correlate with the progenitor of the mapping to redshift space although the correlation is not perfect.

The result of the mapping of the nonlinear progenitor (eq. 3.2) to redshift space is shown as red regions in fig.8. If the linear progenitor was mapped to redshift space it would sit perfectly on top of the nonlinear structure, however it would remain significantly less connected than the nonlinear structure as the mapping is continuous. The figure illustrates a substantial change in the geometry caused by the mapping itself. The sizes of red filaments and voids between them are noticeably greater in redshift space than in Lagrangian space. Some smaller regions seen in Lagrangian space have merged into larger structures when mapped to redshift space. The difference between the structures in Eulerian (fig.4) and redshift space (fig.8) is quite substantial.

Figure 8 also shows the convergence segments of the zero line of the radial velocity field demonstrated in fig.6. Similarly to fig.7 the black dots are noticeably more numerous in red regions than between them. In this case the correlation is not entirely perfect either but it is quite obvious despite the fact that the black dots are plotted in Lagrangian space

Figure 6: Lagrangian space. Contours of $f v_q(\mathbf{q}) > 0$ are shown in red, $f v_q(\mathbf{q}) = 0$ in green and $f v_q(\mathbf{q}) < 0$ in blue. The segments of convergence i.e., the parts of the contour $v_q(\mathbf{q}) = 0$ satisfying the condition $\partial v_q / \partial q < 0$ are marked by black dots.

while the red structure is plotted in redshift space. As we have seen in fig.4 the mapping to Eulerian space does not shift the progenitor much and the following mapping to redshift space does not move the points with $v_q = 0$. In a few cases the separate segments of the convergence set seem to be aligned forming the filaments with total length of over $500 \text{ h}^{-1} \text{Mpc}$. An example of this is the system of five segments that begins at distance about $200 \text{ h}^{-1} \text{Mpc}$ toward $1h$ from the center and continues clockwise down to distance $\sim 150 \text{ h}^{-1} \text{Mpc}$ toward $4h$ from the center.

The correlation between the structure in redshift space and the segments of convergence allows to use the lengths of the segment of convergence as predictors of the length of filaments. Figure 9 shows the segments of convergence i.e., the parts of line $v_q(\mathbf{q}) = 0$ where additional conditions $\partial v_q / \partial q_q < 0$ is satisfied. These lines are attractors of the nonlinear structure in redshift space. Inspecting the figure one can easily identify the lines extended over $500 \text{ h}^{-1} \text{Mpc}$ that suggests the existence of the filaments of similar sizes. The field $s_q(\mathbf{q})$ is closely related to the initial potential since $s_q(\mathbf{q}) = -\partial \Phi / \partial q$ and therefore may be affected by an insufficient size of the box. Thus, the actual size of largest walls can be even greater than suggested by fig.9 in real universe. The full three-dimensional N-body simulations checking this prediction are currently on the way.

3.3 Scales of Gaussian random fields

In cosmology Gaussian fields are often characterized by several scales derived from moments $\langle k^{2j} \rangle \equiv (2\pi^2)^{-1} \int k^{2j} P(k) k^2 dk k^{2j}$ of the power spectrum $P(k)$ (e.g., [23]). The ratios of

Figure 7: Lagrangian space. The nonlinear progenitor of the structure in redshift space defined by the condition eq. 3.2 is shown in red. Green contours show the regions defined by the linear condition $\delta(\mathbf{q}) \geq 1$. Black dots mark the segments of convergence.

these moments generate a set of scales $R_j^2 = 3 \langle k^{2j} \rangle / \langle k^{2(j+1)} \rangle$. Two particular scales $R_1 \equiv R_*$ (using notation of ref. [23]) and R_0 are used the most often as the characteristics of linear density fields. The former is associated with the spatial distribution of peaks and is discussed in detail in [23]. The latter is referred to as the mean distance between crossing points of zero level [30]. [31] introduced the integral length scale $L = \xi^{-1}(0) \int_0^\infty \xi(r) dr = (\pi/2) \int_0^\infty k P(k) dk / \int_0^\infty k^2 P(k) dk$, the physical meaning of which is not quite obvious. An example of using other scales in cosmology is given in [32]. The suggested model deals with the components of the deformation tensor $d_{ij}(\mathbf{q})$ and displacement $s_i(\mathbf{q})$ that are combined into radial components $d_{qq}(\mathbf{q})$ and $s_q(\mathbf{q})$. Here we consider the small angle approximation that fully described by d_{11} and s_1 fields. The scales can be characterized by the distribution of distances between successive zeros of a field along two axes (see e.g., [18]). Figure 10 shows the cumulative probability functions of zero crossing distances for four fields ($\delta = I_1, d_{11}, v_1$ and Φ) along two axes (q_1 and q_2). The density contrast field is isotropic and both cpfs are practically identical. The potential field also must be statistically isotropic but it depends strongly on long wave part of the power spectrum. In fact the variance σ_Φ^2 formally logarithmically diverges at $k \rightarrow 0$. However, this is not a serious physical problem. Heavens [33] pointed out that in a fixed sample volume (e.g., the observable universe) the potential is well behaved, however we cannot determine the global zero level of the potential. He showed that by introducing $\Delta\Phi(\mathbf{x}) = \Phi(\mathbf{x}) - \Phi_0$, where Φ_0 is the value of the potential at the observer location, the problems related to the divergence of σ_Φ^2 are reduced to a weak dependence of the results on unknown value of Φ_0 . Such fields

Figure 8: Redshift space. The large-scale structure is shown in red. The black lines are the parts of the contour $v_q(\mathbf{q}) \equiv v_i(\mathbf{q})\tilde{n}_i(\mathbf{q}) = 0$ selected by the condition $\partial v_q / \partial q < 0$. Two blue arcs mark the central $50 \text{ h}^{-1}\text{Mpc}$ region where the adopted approximation ($D|\mathbf{s}|/q \ll 1$) is not very accurate.

are known as locally homogeneous and locally isotropic fields and are discussed in Sec. 13 of ref. [31]. This dependence of the potential on the long wave part of the spectrum explains huge variations in the tail of the cumulative function seen in fig.10 (black solid lines). The scales along q_2 are much greater than along q_1 for both anisotropic fields d_{11} and v_1 . The level lines of all fields are quite wiggly therefore there are quite a few short distances between crossing points. The overall sizes are probably better characterized by the tails of the distributions. Here are the median and the value marking the top 10% distances along q_1 and q_2 axes for four fields in h^{-1}Mpc : median $\delta(11, 11)$, d_{11} (10, 18), s_1 (21, 31) and Φ (102, 84), top 10% δ (30, 30), d_{11} (21, 54), s_1 (66, 117) and Φ (397, 437).

4. Implications for three-dimensional universe

The progenitor of the mapping to Eulerian space is determined by the interplay of three fields: one Gaussian $\delta = I_1$ and two non-Gaussian I_2 and I_3 . It is easy to show that they do not correlate by the direct calculation of the corresponding integrals over the joint pdf (see Appendix). However the fact that two fields are non-Gaussian does not allow to declare them statistically independent and it makes the further analysis more challenging.

Many features of two-dimensional model although not all are expected to be very similar in three dimensions. Nonlinear term proportional to I_2 helps to fill the gaps between peaks of linear field $\delta = I_1(\mathbf{q}) > 1$ in 2D and therefore boosts the length of filaments in Lagrangian space up to $70 - 100 \text{ h}^{-1}\text{Mpc}$. There is no reason to doubt that it works in

Figure 9: Lagrangian space ($1024 \, h^{-1} \text{Mpc}$ box). The black dots mark the segments of convergence i.e., the segments of contour $v_q(\mathbf{q}) = 0$ where additional condition $\partial v_q / \partial q_q < 0$ is satisfied. These lines are a kind of attractor of the structure in redshift space and their lengths are similar to the lengths of walls.

a similar way in 3D. In addition, the term proportional I_3 in eq. 2.3 is likely to boost the lengths of filaments even more. However, the further study is obviously needed both analytical and numerical.

The mapping to Eulerian space itself does not change significantly the lengths of the filaments and does not displace them much from the initial positions in 2D. The mapping in 3D is expected to be similar in this respect.

However, the mapping to redshift space differs in 3D significantly in a few respects. All three fields d_{qq} , M_{qq} (see eq. 2.9) and s_q (see eq. 2.6) have scales in the radial direction much shorter than in two transverse directions. This causes the progenitor and the structure in redshift space to acquire a circular pattern in 2D while it gives rise to the origin of shell like walls in 3D. The walls in redshift space expected to be neither homogeneous nor thin but their transverse sizes must be considerably greater than the radial thickness. Similarly to the two-dimensional case the greatness of 'great walls' comes from anisotropy of two Gaussian fields d_{qq} and s_q and in addition one non-Gaussian field, M_{qq} derived from initial Gaussian field. As fig. 10 indicates the transverse coherence of both d_{11} and especially s_1 field can easily exceed $100 \, h^{-1} \text{Mpc}$. Two isotropic non-Gaussian fields I_2 and I_3 also contribute to the formation of the structure in redshift space since the corresponding terms are boosted by factor $1 + f$ in the Jacobian J_ζ (eq. 2.9).

The convergence lines defined in 2D become the convergence surfaces in 3D, they are expected to provide a reasonable estimate of the transverse sizes of great walls.

Figure 10: Cumulative probability function of the zero-crossing distances along two axes q_1 and q_2 . The top dotted line marks the median values of the probability functions.

5. Summary and discussion

We propose a new theoretical model that describes the formation of the large-scale structure in redshift space. It naturally explains the sizes of the observed great walls and predicts that even greater walls will be discovered in future deeper and larger redshift surveys. Although based on the Zel'dovich approximation [26] the suggested model uses it in a new and very different way. Instead of traditional approaches that focused on the evaluation of density or positions and velocities of the particles we introduce the notion of the progenitor of the large-scale structure. It is defined as a set of regions in Lagrangian space that after mapping to Eulerian or redshift space (depending on the kind of mapping we study) end up in the regions where the particle trajectories have crossed and the mapping is no longer unique. Neglecting the thermal velocities and assuming smooth initial condition the boundaries of these regions in Eulerian or redshift space are caustics. In reality due to hierarchical clustering process the caustics do not form but the density of both matter and galaxies is still highest in these regions (eg [25]). Even in the case of smooth initial conditions the evaluation of the density within the shell-crossing regions is not easy and we do not attempt to estimate it in this paper. Instead we utilize the Zel'dovich approximation for identification of the progenitor of the structure in Lagrangian space and then for mapping it to Eulerian or redshift space. In particular we demonstrate the role of various fields some of which are non-Gaussian or/and anisotropic. This is the most important factor in explanation of the lengths of filaments in Eulerian space. Non-Gaussian $I_2(\mathbf{q})$ and $I_3(\mathbf{q})$ fields fill the gaps between peaks of Gaussian $\delta(\mathbf{q}) = I_1(\mathbf{q})$ field significantly boosting the length of the progenitor of the filaments in Lagrangian space. It is worth stressing that the mapping of the progenitor to Eulerian space does not increase its lengths noticeably

although it significantly affects its appearance.

The mapping to redshift space has both the progenitor in Lagrangian space and the structure in redshift space significantly different than the mapping to Eulerian space. In both cases the thickness of the filaments in Eulerian space and walls in redshift space is probably the least accurate in this approximation. The thickness of filaments in Eulerian space is probably exaggerated [27]. The thickness of the walls in redshift space may be affected by nonlinear effects that change the velocities in the shell-crossing regions. However, the estimate of the extent of the walls in the transverse direction is expected to be quite robust.

Although both the suggested model and one suggested by [6] (BKP) are based on the Zel'dovich approximation (eq. 2.1) there are a few radical differences between them. The current model can explain the sizes of both the structures in Eulerian and redshift space emphasizing that the structure in redshift space must have significantly greater sizes in transverse directions than in the line of sight direction and therefore the wall kind structures must be more conspicuous in redshift space. The BKP model discusses only the structure in Eulerian space. The BKP model uses the smoothing scale R_b defined by an inequality $\sigma_\delta(R_b) \lesssim 1$ such that it corresponds to "the conceptual picture of a smooth stately large-scale single-stream flow" [6] while the current model uses the scale of nonlinearity and therefore assumes the crossing of trajectories and presence of multi-stream flows. Although it is not excluded that the further comparison with cosmological N-body simulations may slightly change the scale for better fit to N-body simulations it will not change the basic construction used by the model - the progenitor of the structure. The model defines the progenitor of the structure as a set of regions in Lagrangian space where the Jacobian of the mapping becomes negative indicating that these regions end up in multi-stream flow regions after mapping to Eulerian or redshift space. There is also one more principal difference. The BKP model uses only linear i.e., Gaussian fields and conditional correlations between them. This model utilizes both non-Gaussian fields (I_2, I_3, M_{qq}) one of which is anisotropic as well as anisotropic Gaussian fields d_{qq}, s_q along with linear density contrast field. The displacement fields s_i and s_q also play important roles in the appearances of the structure in Eulerian and redshift spaces. The suggested approach allows easily to isolate the role of every field and thus helps to better understand the complex nonlinear dynamics of the structure formation.

Further studies including the more detailed studies of the statistical properties of the fields involved in the mappings as well as a direct comparison with cosmological N-body simulations are obviously needed. Some work has already started and the results will be reported in the following papers.

Acknowledgments

I would like to acknowledge many useful discussions I had during last several years with J. R. Bond, U. Frisch, S. Habib, K. Heitmann, L. Kofman, A. S. Szalay, R. Triay, B. Tully, and R. van de Weygaert that helped me greatly in developing this model. I am also grateful to the anonymous referee for constructive and useful comments.

A. Appendix: PDF of invariants I_1, I_2 and I_3

From eq. 12 in [29] it is easy to derive the joint distribution of three invariants if one notes that $dI_1 dI_2 dI_3 = (\lambda_1 - \lambda_2)(\lambda_1 - \lambda_3)(\lambda_2 - \lambda_3)d\lambda_1 d\lambda_2 d\lambda_3$ (λ_i and I_1 are measured in units of σ_δ , I_2 in units of σ_δ^2 and I_3 in units of σ_δ^3)

$$p(I_1, I_2, I_3) = \frac{675\sqrt{5}}{8\pi} \exp(-3I_1^2) F_2(I_1, I_2) F_3(I_1, I_2, I_3), \quad (\text{A.1})$$

where

$$F_2(I_1, I_2) = \exp\left(\frac{15}{2}I_2\right), \quad \text{if } I_2 < I_1^2/3 \text{ and } 0 \text{ otherwise,}$$

$$F_3(I_1, I_2, I_3) = 1, \quad \text{if } I_3^{(2)} < I_3 < I_3^{(1)} \text{ and } 0 \text{ otherwise}$$

The constraints on I_3 reflect the fact that all three λ_i are real which requires that $\Delta(I_1, I_2, I_3) < 0$, where

$$\Delta(I_1, I_2, I_3) = 27I_3^2 - 2I_1(9I_2 - 2I_1^2)I_3 + I_2^2(4I_2 - I_1^2). \quad (\text{A.2})$$

Therefore, I_3 must lie between the roots of the equation $\Delta(I_1, I_2, I_3) = 0$ which are

$$I_3^{(1,2)} = \frac{1}{27} \left[I_1(9I_2 - 2I_1^2) \pm 2(I_1^2 - 3I_2)^{3/2} \right]. \quad (\text{A.3})$$

The constraint on I_2 is a trivial consequence of relations between the eigen values λ_1, λ_2 and λ_3 and the invariants: $I_1 = \lambda_1 + \lambda_2 + \lambda_3$, $I_2 = \lambda_1\lambda_2 + \lambda_1\lambda_3 + \lambda_2\lambda_3$ and $I_3 = \lambda_1\lambda_2\lambda_3$. Thus, the distribution of I_3 for given I_1 and I_2 is uniform in the range $I_3^{(2)} < I_3 < I_3^{(1)}$. The distribution of I_2 for given I_1 and I_3 is exponential in the range $-\infty < I_2 < I_1^2/3$ and the distribution of I_1 for given I_2 and I_3 is Gaussian. Integration over I_3 gives the joint distribution of I_1 and I_2

$$p(I_1, I_2) = \frac{25\sqrt{5}}{2\pi} \exp(-3I_1^2) \exp\left(\frac{15}{2}I_2\right) (I_1^2 - 3I_2)^{3/2}, \quad (\text{A.4})$$

and then the integration over I_2 gives the Gaussian distribution of the linear density contrast since $\delta = DI_1$ in the linear regime. It is not difficult to check that the invariants do not correlate at one point: i.e., $\langle I_1 I_2 \rangle = 0$, $\langle I_1 I_3 \rangle = 0$ and $\langle I_2 I_3 \rangle = 0$.
